21 ***Abstract***

22 On March 2023, a Mw6.6 intraplate earthquake with epicenter in the Gulf of Guayaquil
23 impacted the coastal region of Ecuador, causing at least 13 deaths, 89 destroyed buildings
24 and 192 affected structures. In several locations around the epicenter of the event,
25 expressions of liquefaction were documented. In order to assess the applicability of
26 liquefaction potential evaluation models, one seismic dilatometer test (SDMT) and one
27 cone penetration test (CPTu) were performed in Puerto Baquerizo (South coastal region
28 of Ecuador, 35 km far from the epicenter), where evidence of earthquake-induced soil
29 liquefaction was clearly observed. In addition, morphological and componentry
30 characterization were carried out in samples of the ejected material retrieved during the
31 exploration program. The liquefaction assessment results in terms of safety factors and
32 liquefaction potential indices reveal that the probability of liquefaction triggering is
33 adequately predicted at the study site by the methodologies based on the SDMT and CPTu
34 data.

54 **1. Introduction**

55 In recent decades great efforts have been dedicated to the development of
56 methodologies that allow reliable prediction of the liquefaction potential, as well as
57 strategies to mitigate its effects in engineering projects. The most widespread procedures
58 in practice are those that are based on field test results. These methods focus on
59 approximating the cyclic resistance of the material using empirical correlations with field
60 test results, and on comparing them with the shear stress levels that are expected to be
61 induced by a specific seismic event [1-3].

62 The applicability of these procedures is constantly evaluated, by determining whether
63 the occurrence and/or severity of liquefaction predicted by the different models coincides
64 with the liquefaction expressions observed in new case studies. However, although
65 Ecuador is a highly seismic country, there are few cases where earthquake-induced soil
66 liquefaction has been well-documented with observations and field tests. The 2016
67 Mw7.8 Pedernales earthquake, an interplate subduction earthquake occurred off the coast
68 of Manabi, Ecuador, being the primary source of case histories [4-9] .

69 This paper aims to compare the predicted levels of liquefaction severity in Puerto
70 Baquerizo City, near Balao, using piezocone test (CPTu) and seismic dilatometer test
71 (SDMT) results with the actual ground damage observed after the 2023 Mw 6.6
72 earthquake. The earthquake occurred at a depth of 66.4 kilometers, approximately 10
73 kilometers from Balao in the province of Guayas. Additionally, the grain size and
74 morphological analysis of two samples of ejected recovered sand are also presented for
75 the case study.

76

77 **2. Geological Setting of Puerto Baquerizo**

78 In the inner estuary of the Gulf of Guayaquil, lithological units of Cretaceous, Tertiary
79 ages emerge, and are mostly covered by Quaternary sediments, of alluvial, alluvial-
80 estuarine, and alluvial-colluvial types [10].

81 The bedrock belongs to the Pallatanga geological formation, predominantly consisting
82 of Cretaceous basalt, which generates hornfels upon contact with the Chaucha batholith
83 [11]. Upper Cretaceous (Senonian-Maastrichtian) volcano-sedimentary rocks have minor
84 outcrops on some islets in the inner estuary of Guayaquil. On Puná Island, other
85 lithological sedimentary units from geological formations (Miocene-Pliocene age) such
86 as Cerro Mala, Placer, Lechuza, and Puná are delineated [12].

87 The marine sedimentary sequences, belonging to the Angamarca Group of the
88 Paleogene, are in unconformity over the oceanic basement. These sequences include
89 turbiditic sediments with ash intercalations [11]. Recent alluvial deposits, alluvial-
90 estuarine and alluvial-colluvial, are composed of clays, sands, and gravels, containing a
91 large amount of eroded materials transported from the northern Andes. These deposits
92 form alluvial fans. The estuarine alluvial deposits correspond to salt flats composed of
93 mud and intervals of fine sand and silts, forming slightly elevated alluvial terraces. The
94 thickness of the alluvial deposits could reach several hundred meters [10].

95 In the Balao area, the sands are poorly sorted, very asymmetrical towards coarse sizes,
96 mesokurtic to very leptokurtic, unconsolidated, with common fragments of coal and
97 phlogopite, rare fragments of resin, deposited under low energy conditions due to the tidal
98 influence of the intertidal zone. The silts and sandy silts are poorly sorted, very
99 asymmetrical towards fine sizes, platykurtic. The sedimentary environments of these
100 sediments are associated with coastal channel types, transitional mangrove and subtidal
101 estuary [13-14].

102 The Pallatanga fault has a NE-SW orientation and traverses the Gulf of Guayaquil and
103 along Puná Island to the ocean trench [15]. East of Puná Island, there is the Jambelí
104 system whose structures are dominated by the Puerto Balao fault with a NE-SW direction,
105 marking the southern boundary of the Jambelí basin [16]. South of Balao, the Río Chico
106 fault is present with a predominantly E-W trend and normal kinematics. The Figure 1
107 shows the geological setting in the areas near the epicenter of the Mw6.6 Balao
108 earthquake and the Gulf of Guayaquil.

Figure 1 Overview map of the inner estuary of the Gulf of Guayaquil (modified from Aleman, [12])

3. Seismotectonic background and 2023 Mw6.6 Balao earthquake

The Gulf of Guayaquil, located on the southern coast of Ecuador bordering Peru, is subject to the dynamic deformation caused by the subduction of the Nazca plates, the continental segment of the Norandine Block and the South American plate [17]. In this seismic scenario, there are documented interplate subduction earthquakes with focal mechanisms associated to compression stresses (1901 Mw7.1 and 1942 Mw7.6 earthquakes), and intraplate associated with focal mechanisms associated to traction stresses (1913 Mw7.4 Zaruma earthquake) [18-19].

Another seismic scenario is associated with the deformation zone between the Norandino Block and the South American plate, where the mechanisms are associated to strike-slip vertical displacements [20]. The deepest focal distances can be between 60 to 70 km. A third seismic scenario is associated to geological faults with the potential to generate moderate earthquakes (between $6 \leq Mw \leq 7.1$) and peak ground accelerations (PGAs) ranging between 0.33 g and 0.36 g [21]. Many of these geological structures are associated with normal and strike-slip faults, where focal distances can be less than 16 km. The closest distance to the ruptures (Rrup) considered for seismic hazard analysis applied to the main Ecuadorian cities, should be considered between 32 to 15 km distances.

131 Chunga et al. [21] provides the cartography of the active geological faults with the
132 potential to generate moderate to high earthquakes in the influence zone of the Gulf of
133 Guayaquil. To estimate the moment magnitude (M_w) of the earthquake that could be
134 generated by the faults identified by Chunga et al. [22], considering 100% and 60% of its
135 seismic activation (according to the NEC-11 regulations; 2015), the Wesnousky model
136 [23] has been used for each type of geological fault (Eq. 1 for strike slip fault and Eq. 2
137 for normal fault):

$$M_w = 5.56 + 0.87 \cdot \text{Log}(L_f) \quad (1)$$

$$M_w = 6.12 + 0.47 \cdot \text{Log}(L_f) \quad (2)$$

138 where L_f represents the length of the fault of interest.

139 Another intensity parameter evaluated by Chunga et al. [24] is the PGA in rock,
140 applying the equation proposed by Fukushima & Tanaka [25]. These values of maximum
141 accelerations in rocks are comparable with the seismic zoning map of Ecuador
142 (Ecuadorian Construction Code NEC, 2011). The equation is detailed as follows:

$$PGA_{rock} = (10^{0.41M_e - \log_{10}(H_f + 0.032 \cdot 10^{0.41M_e})} - 0.0034H_f + 1.3)/980 \quad (3)$$

143 The historical earthquakes with higher magnitude close to the internal coast of the Gulf
144 of Guayaquil, are: [a] M_w 5.7 July 9, 1653 with estimated depth less than 10 km; [b] M_w
145 6.5 June 11, 1787 with estimated depth 15 km, [c] M_w 6.2 March 12, 1962, [d] M_w 5.5
146 August 18, 1980 with estimated depth 15 km, [e] M_w 5.3 April 26, 1995; depth 19 km).
147 [f] M_w 5.3 April 26, 1995; depth 19 km. The M_w 6.2 1961 earthquake with estimated
148 hypocenter depth of about 33 km is considered an intraplate event. The earthquakes of
149 March 12, 1962 (M_w 6.2) and March 18, 2023 (M_w 6.6, depth of 68 km) are considered
150 a horizontal shear mechanism, associated with the displacement between the Norandino
151 block and the South American plate.

152 The recent 2023 M_w 6.6 earthquake severely affected in the provinces of El Oro (129
153 affected and 78 destroyed buildings), Guayas (49 affected and 7 destroyed buildings),
154 Azuay (14 affected and 4 destroyed buildings), and extent to Loja, Los Rios, Bolívar,
155 Cañar and Chimborazo. In total 192 affected and 89 destroyed buildings have been
156 documented, and at least 13 deaths and 484 injuries were recorded. The epicenter was
157 located at the decimal degree coordinates of -2.752° N, -79.881° E, with a focal depth of
158 63 km, strike 135° , dip 88° and rake 148° .

159 In urban areas such as Puerto Baquerizo (a. in Figure 2), Machala (b. in Figure 2) and
160 Mondragon Islet (c. in Figure 2) clear evidence of earthquake-induced soil liquefaction

161 was observed after the Mw6.6 Balao earthquake. The identified expressions of
 162 liquefaction include the presence of sand volcanoes, ground cracking and evidence of
 163 damage in structural and non-structural elements of buildings near the sites where the
 164 manifestation of ground liquefaction was observed.

 171 ground acceleration (PGA-H) recorded by the Ecuadorian Accelerograph Network
 172 Stations (IGEPN) in Balao earthquake

173 **3.1. Grain size analysis**

174 In order to study the composition and classification of the sandy material ejected to
 175 the surface in Puerto Baquerizo, grain-size analysis was carried out according to the
 176 ASTM C-136-01 [26]. The tests were performed on two samples recovered in different
 177 sand volcanoes. The samples of ejected material correspond to a non-plastic poorly
 178 graded silty sand (SP-SM according to the Unified Soil Classification System, USCS,
 179 [27] and a non-plastic poorly graded sand (SP), with fines content (FC) of 6.6% and 4.5%,
 180 respectively. As shown in Figure 3, between 85% and 90% of the sieved material

181 corresponds to fine sand (0.075-0.425 mm of grain size), while a limited fraction of the
 182 samples corresponds to a medium sand (0.425-2 mm of grain size). The Table 1
 183 summarizes the characteristic diameters of the 10%, 30% and 60% of the particles,
 184 namely D_{10} , D_{30} and D_{60} respectively, and the coefficient of uniformity (C_u) and of
 185 curvature (C_c).

186

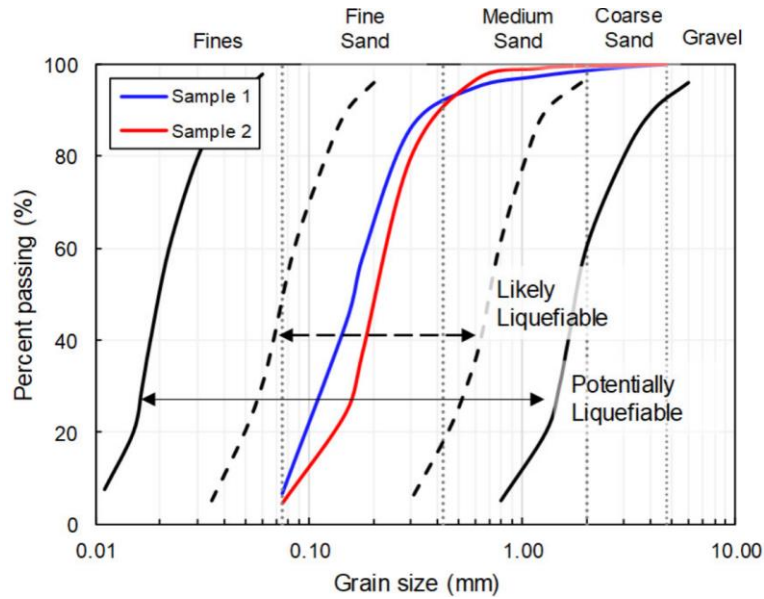

187 Table 1 Grain-size properties of the ejected sand material in Puerto Baquerizo

Sample	USCS	D_{10} (mm)	D_{30} (mm)	D_{60} (mm)	C_u (-)	C_c (-)	FC (%)
Sample 1	SP-SM	0.082	0.122	0.187	2.28	0.97	6.63
Sample 2	SP	0.096	0.162	0.244	2.55	1.13	4.54

188

189 The material recovered from Puerto Baquerizo presents grain sizes between 2 and 5
 190 times larger than the sand boils samples obtained in Boca de Briceño (central-coastal of
 191 Ecuador with ejecta classified as silty sand) after the liquefaction induced by the Mw7.8
 192 Pedernales earthquake [7]. In the same way, the fines content measured in the soils
 193 recovered from Puerto Baquerizo is notably lower than that of the ejected sand in Boca
 194 de Briceño ($FC > 35\%$).

195 The uniformity of the ejected sands in Puerto Baquerizo could be explained due to the
 196 pulse flows generated in the dikes and subsequent extrusion of the material to the surface
 197 during the liquefaction process [28]. Therefore, the granulometric distribution and the
 198 fines content observed in the material recovered on the surface may not be representative
 199 of the source layer.

200

201 Figure 3 Grain size distribution of samples of ejected sand in Puerto Baquerizo and the
 202 boundaries of potentially liquefiable material from Tsuchida and Hayashi [29]

203 **3.2.Morphological analysis**

204 For morphological evaluation additional grain-size analyses were carried out in the
 205 present study. Samples were dry-sieved using sieves #30 (0.6 mm), #50 (0.3 mm), #80
 206 (0.180 mm), and #100 (0.150 mm). Morphological and componentry analyses were
 207 conducted on the four grainsize ranges depicted in the high-resolution photo (...).

208 For morphological analyses, an average of 500 clasts were measured using Image-J
 209 software via image analysis to determine area, perimeter, major and minor axes, and
 210 circularity. Between the 70% and 80% of the soil particles analyzed corresponded to
 211 rounded grains with circularity coefficient between 0.70 and 0.90. The particles retained
 212 on sieves #80 and #100 had approximately 10% more rounded particles than the rest of
 213 the analyzed samples. Sands with uniform rounded particles are highly susceptible to
 214 liquefaction, since they tend to have higher void ratios and to develop greater volumetric
 215 deformations [30-31].

216 Component analyses were performed through point counting on high-resolution
 217 images taken under transmitted-light microscopy within the selected grain-size fraction.
 218 All samples contained a minimum of 500 clusters. Six main compositional categories
 219 were identified: Quartz (mainly as free crystals), Feldspar (principally as K-Feldspar),
 220 Metamorphic rock fragments, Volcanic rock fragments, Mica (muscovite), and Calcite
 221 fragments. The counting process was conducted using automatic particle selection
 222 through the Image-J program, with adjustments made to the image threshold to facilitate

223 color-based segmentation of particles for each category. Results are presented in Figure
 224 4 using the Q (quartz) + F (feldspars), L (siliciclastic lithics) and C (carbonate) diagram
 225 and in the Q (quartz), F (feldspars), and L (siliciclastic lithics) + C (carbonate) diagram.

226

227 Figure 4 Ternary diagrams (Q, F, L+C and Q+F, L, C) showing the morphological
 228 composition of the ejected sand in Puerto Baquerizo

229 **4. Site campaign**

230 The site investigation program consisted of performing one SDMT test and one CPTu
 231 where the effects of liquefaction were most evident, close to the sand volcanoes shown
 232 in the **¡Error! No se encuentra el origen de la referencia..** For the SDMT the corrected
 233 lift off (p_0) and 1.1 mm deformation pressures (p_1) were measured every 0.2 m up to 20
 234 m depth, while the equilibrium pressure after deflation (p_2) was carried out at levels where
 235 the presence of materials with drained behavior was encountered, detecting the ground
 236 water table (GWT) at 1.8 m from the surface. The shear wave velocity (V_S)

237 measurements were carried out each 0.5 m up to 8 m depth, and each 1.0 m between 8 m
238 and 17 m depth.

239 For the CPTu the cone resistance (q_c), sleeve friction resistance (f_s) and the pore
240 pressure (u_2) were measured each 0.01 m until 20 m depth, identifying the GWT at 1.5
241 m. As well as in the SDMT, dissipation tests were carried out when the presence of
242 drained materials was observed. The equilibrium hydrostatic pressures measured at the
243 end of the dissipations confirmed the observed depth of the GWT at 1.5 m. The different
244 GWT recorded by SDMT and CPTU can be due to the GWT seasonal fluctuation
245 considering that the SDMT was performed in August 2023 while the CPTu in December
246 2023, in the beginning of the rainy season on the Ecuadorian coast.

247 The Figure 5 and Figure 6 shows the parameters measured and interpreted from both
248 tests carried out. In particular Figure 5 plots the profile of SDMT parameters in terms of:
249 the material index (I_D); the fines content (FC) according to Di Buccio et al. [33] ; the
250 horizontal stress index (K_D); the corrected lift off pressure (p_0) and the 1.1 mm deflection
251 pressure (p_1); the corrected equilibrium pressure after deflating (p_2) and the hydrostatic
252 pore water pressure (u_0); and the shear wave velocity (V_s) measured in the SDMT and
253 estimated from the DMT [34-35] and CPTu data [36]. For CPTu Figure 6 reports the
254 following parameters: soil behavior type index (I_c); fines content (FC) according to
255 Boulanger and Idriss [3] and Suzuki. [37]; corrected cone resistance (q_t); normalized
256 friction ratio (Fr); and pore water pressure excess (u_2) and hydrostatic pore pressure.

257 By comparing the soil profiles, it can be noticed that there is a good agreement in the
258 classification of the material determined by I_D from DMT and I_c from CPTu, identifying
259 cohesive or cohesionless behaviors at similar depths. Both tests identify the presence of
260 sandy layer with 3.9 m of thickness, underlying a cohesive crust. The beginning of the
261 sandy layer is located at 2.6 m by the SDMT and at 2.9 m by the CPTu, while the end of
262 the incoherent layer is located at approximately 6.5 m by both tests. Both tests identify
263 that under the sandy layer there are fine intercalations of granular materials with cohesive
264 layers up to 14 m depth. However, none of these intercalations has sufficient thickness to
265 be considered a well-defined sandy geotechnical unit.

266 In the sandy interval I_D slightly ranges between 1.70 and 2.10, while K_D and V_S show
267 a significant increase between 4.5 m and 6 m depth, reaching magnitudes between 6 and
268 7.5 for K_D and between 120 and 150 m/s for V_S . At the upper and lower boundaries of
269 the sandy layer the K_D values tend to be between 3 and 4, while V_S is between 110 and
270 160 m/s.

271 On the other hand, for CPTu in the sandy layer I_c varies between 1.6 and 1.8 while q_t
 272 is between 2.3 and 5.5 MPa, and F_r is approximately 0.20%. The lowest values of the
 273 corrected cone penetration resistance (q_t) were measured in the same depth interval
 274 (between 2.5 m and 3.0 m depth) where the SDMT detected the lowest values of the
 275 horizontal stress index (K_D). However, from 4.2 m depth the resistance to penetration of
 276 the CPTu cone shows little variability, being 4 MPa the average magnitude. No marked
 277 peaks from CPTu are observed around 5 m depth, where maximums of K_D were
 278 estimated.

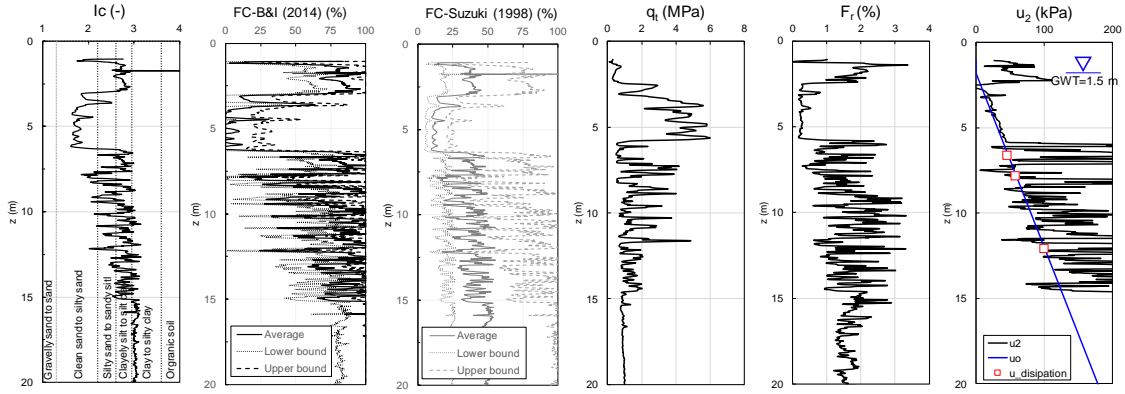

279 In order to approximate the fines content (FC) of the sandy materials prior to proceed
 280 to the liquefaction assessment, the estimations provided by the I_D -FC and the I_c -FC
 281 correlations were compared, observing a great variability. The Figure 5 shows that in the
 282 region where sandy material is detected, the I_D -FC model from Di Buccio et al. (2023)
 283 provides fines content between 25% and 40%. Instead Suzuki [37] at the same depth
 284 interval determines FC that vary slightly around 8% and 25%, while Boulanger and Idriss
 285 [3] indicate the presence of a clean sand, with fines content ranging between 0 to 25%, as
 286 is shown in the Figure 6.

291

5. Liquefaction potential assessment

292

5.1. Cyclic resistance ratio estimation

293

To calculate the cyclic resistance ratio ($CRR_{7.5}$) were selected a set of methodologies that use the information provided by the SDMT and CPTu tests as input. In general, the methods selected for the development of this case study are classified as follows: (i) methods based on the horizontal stress index (K_D) using only DMT information (Monaco et al. [38], Eq. 3; Tsai et al. [39], Eq. 4; Robertson et al. [40], Eq. 5; Marchetti [41], Eq. 6; Chiaradonna and Monaco [42], Eq. 6); (ii) methods based on the overburden corrected penetration resistances for clean sand (q_{c1Ncs}) using only CPTu information (Idriss and Boulanger [2], Eq. 8; Boulanger and Idriss [3], Eq. 9); (iii) methods that combine the use of the DMT and CPTu information (Marchetti [41], Eq. 10) and (iv) methods that use the overburden corrected shear wave velocity (V_{s1} , Andrus and Stokoe [43], Eq. 11; Kayen et al. [44], Eq. 12).

304

$$CRR_{7.5} = 0.0107 \cdot K_D^3 - 0.0741 \cdot K_D^2 + 0.2169 \cdot K_D - 0.1306 \quad (3)$$

305

$$CRR_{7.5} = \exp \left[\left(\frac{K_D}{8.8} \right)^3 - \left(\frac{K_D}{6.5} \right)^2 + \left(\frac{K_D}{2.5} \right) - 3.1 \right] \quad (4)$$

306

$$CRR_{7.5} = 93 \cdot (0.025 \cdot K_D)^3 + 0.08 \quad (5)$$

307

$$CRR_{7.5} = \exp[0.2192 \cdot K_D^4 - 0.3125 \cdot K_D^3 + 0.3731 \cdot K_D^2 + 0.0462 \cdot K_D - 3] \quad (6)$$

308

$$CRR_{7.5} = \exp(0.0011097 \cdot K_D^4 - 0.0057 \cdot K_D^3 + 0.00062 \cdot K_D^2 + 0.22 \cdot K_D - 2.8) \quad (7)$$

309

$$CRR_{7.5} = \exp \left[\left(\frac{q_{c1n cs}}{540} \right) + \left(\frac{q_{c1n cs}}{67} \right)^2 - \left(\frac{q_{c1n cs}}{80} \right)^3 + \left(\frac{q_{c1n cs}}{114} \right)^4 - 3 \right] \quad (8)$$

310

$$CRR_{7.5} = \exp \left[\left(\frac{q_{c1n cs}}{113} \right) + \left(\frac{q_{c1n cs}}{1000} \right)^2 - \left(\frac{q_{c1n cs}}{140} \right)^3 + \left(\frac{q_{c1n cs}}{137} \right)^4 - 2.80 \right] \quad (9)$$

311 $CRR_{7.5} = [(CRR_{7.5} \text{ from } q_{c1Ncs}) \cdot (CRR_{7.5} \text{ from } K_D)]^{0.5}$ (10)

312 $CRR_{7.5} = \left[0.022 \cdot \left(\frac{V_{s1}}{100} \right)^2 + 2.8 \cdot \left(\frac{1}{V_{s1}^* - V_{s1}} - \frac{1}{V_{s1}^*} \right) \right]$ (11)

313 $CRR_{7.5} = \exp\left\{ \left[(0.0073 \cdot V_{s1})^{2.8011} - 2.6168 \cdot \ln(M_w) - 0.0099 \cdot \ln(\sigma'_{vo}) + 0.0028 \cdot \right. \right.$
 314 $\left. FC - 0.4809 \cdot \Phi^{-1}(P_L) \right] / 1.946 \}$ (12)

315 The DMT data were filtered to calculate the $CRR_{7.5}$ only in the soils where $I_D \geq 1.2$,
 316 where $I_D = 1.2$ represents the boundary between silts and sandy silt according to Marchetti
 317 and Crapps [45], while the CPTu data were filtered for $I_c \leq 2.6$, since $I_c = 2.6$ is
 318 approximately the threshold between clayey silt to silty clay and silty sand to sandy silt.
 319 However, although models that correlate FC with I_D and I_c are widely used in
 320 geotechnical engineering practice, there is large uncertainty regarding whether these
 321 values adequately fit to the FC of Ecuadorian soils. No research has been developed to
 322 calibrated these models with FC from laboratory tests. Therefore, there is a possibility
 323 that certain potentially liquefiable materials are not being adequately considered within
 324 the present analysis, especially those with I_D and I_c slightly less than 1.2 and higher than
 325 2.6, respectively. Further research it is necessary in order to calibrate the models of Suzuki
 326 [37], Boulanger and Idriss [3] and Di Buccio et al. [33].

327 The DMT methodologies were developed by the authors considering the close
 328 relationship between the K_D and the parameters directly related to the liquefaction
 329 potential such as the relative density (D_r), the in-situ earth pressure coefficient (K_0), and
 330 the overconsolidation ratio (OCR, [38, 46-50]);. Most of these expressions were derived
 331 using existing $CRR_{7.5}$ models available from Standard Penetration Test (SPT) or Cone
 332 Penetration Test (CPT), and replacing their variables (overburden corrected penetration
 333 resistances for clean sand, i.e. N_{160cs} for SPT and q_{c1Ncs} for CPT) with the equivalent
 334 values from the K_D .

335 The models proposed by Boulanger and Idriss [3] were developed with robust in situ
 336 background, including in the database recent historical cases of liquefaction assessment
 337 in events such as 2010-2011 Canterbury earthquake sequence, 2011 Mw9 Tohoku
 338 earthquake.

339 Considering the availability of CPTu and SDMT data, carried out at nearby sites, the
 340 Marchetti [41] q_{c1Ncs} - K_D based model was introduced into the analysis. This method
 341 defines the cyclic resistance rate as the geometric mean between the resistances calculated
 342 from methods based on cone resistance (Boulanger and Idriss [2], according to Marchetti,

343 [41]) and those determined by the K_D -based method, as is detailed in the Eq.9. Since the
 344 frequency of data acquisition diverges between the DMT and CPTu tests (DMT data
 345 every 0.20 m, and CPTU data every 0.01 m), the q_{c1Ncs} values were averaged around the
 346 levels where the DMT data were obtained. In this way, the average cyclic resistance ratio
 347 calculated with Idriss and Boulanger [2] takes into consideration the behavior of the
 348 materials above and below each depth of analysis. For this method, only those materials
 349 with $I_D \geq 1.20$ and an average $I_c \leq 2.6$ were considered as soils with sand-like behavior.

350 Finally, regarding the V_S -based simplified methods the Andrus and Stokoe [43]
 351 includes a shear wave velocity value corrected for the fines content (V_S^*), while the
 352 Kayen et al. [44] model includes also a probabilistic term, which is the inverse cumulative
 353 normal distribution $\Phi^{-1}(P_L)$, defined to a liquefaction probability (P_L) of 15%. The FC
 354 estimates were derived from the Di Buccio et al. [33] model, as a differentiation criterion
 355 between soils with sand-like or clay-like behavior, as well as for the calculation of the
 356 $CRR_{7.5}$ from Andrus and Stokoe [43] and Kayen et al. [44] equations.

357 5.2.Cyclic stress ratio estimation

358 The cyclic stress ratio corrected for a Mw7.5 and an overburden stress of 1 atm ($CSR_{7.5, 1 \text{ atm}}$)
 359 was determined by applying the simplified procedure proposed by Seed and Idriss
 360 [51]. This model indicates that the $CSR_{7.5, 1 \text{ atm}}$ could be determinate from the following
 361 expression:

$$362 \quad CSR_{7.5, 1 \text{ atm}} = 0.65 \cdot \left(\frac{a_{\max}}{g}\right) \cdot r_d \cdot \left(\frac{\sigma_{v0}}{\sigma'_{v0}}\right) \cdot \frac{1}{MSF \cdot K_\sigma} \quad (13)$$

363 Where the term a_{\max} is the maximum horizontal acceleration at surface, g is the gravity,
 364 r_d is the shear stress reduction coefficient, MSF is the magnitude scale factor, K_σ is the
 365 overburden correction factor, while σ_{v0} and σ'_{v0} represents the total and effective stress.
 366 The σ'_{v0} was computed assuming a safe GWT at 1.5 m. This assumption takes into
 367 account that March (when the earthquake occurred) is part of the rainy season in the Coast
 368 of Ecuador, and the test was performed in months where low levels of precipitations exist
 369 in the area.

370 For the CPT-based and DMT+CPT-based methods, the r_d and K_σ values were
 371 estimated according to Idriss and Boulanger [2]. Since there are no models that correlate
 372 K_σ with the parameters measured or interpreted from the DMT, the values calculated of
 373 K_σ from the CPTu were considered for the estimation of the seismic demand for the DMT-
 374 based methods. While the magnitude scale factor (MSF) was computed using the

375 Boulanger and Idriss [3] relationships with the $q_{c1n\ cs}$ calculated from the results of the
 376 CPTu test.

377 The Andrus and Stokoe [44] method was synthesized using the stress reduction
 378 coefficient (r_d) and magnitude scale factor (MSF) relationships recommended by the
 379 NCEER Workshop [52]. To be consistent with the considerations made by the author, the
 380 same relationships of the NCEER Workshop model [52] were used for the calculation of
 381 the seismic demand in the evaluation of the liquefaction potential based on the Andrus
 382 and Stokoe method [43]. The overburden correction factor (K_σ) was assumed equal to 1
 383 for the liquefaction assessment from Andrus and Stokoe [43]. For the Kayen et al. [44]
 384 method, the specific relationships proposed by the author were used to calculate the stress
 385 reduction coefficient and the magnitude scale factor.

386 The last important issue to estimate the cyclic stress ratio ($CSR_{7.5, 1\ atm}$) was the
 387 quantitative evaluation of the maximum horizontal acceleration during the Mw6.6
 388 earthquake. The estimation in Puerto Baquerizo was carried out by applying the Ground
 389 Motion Prediction Equations (GMPEs) proposed by different authors for in-slab
 390 earthquakes. This decision was made since the closest station of the Ecuadorian
 391 Accelerograph Network to the study site are between 60 and 70 km away, and with
 392 slightly greater epicentral distances. Therefore, their measurements were not considered
 393 representative of the accelerations induced in Puerto Baquerizo. However, by having both
 394 the epicentral distance and the recorded horizontal accelerations well documented, the
 395 information provided by the Ecuadorian Accelerograph Network represented an
 396 important database for the validation of the predictions made by the GMPEs.

397 The Table 2 summarizes the peak horizontal ground acceleration (a_{max}) recorded by
 398 the closest accelerograph stations, the estimated epicentral distance (R) and the referential
 399 geological setting for each site.

400

401 Table 2 Ground motions recorded by the Ecuadorian Accelerograph Network stations
 402 during the Mw6.6 Balao Earthquake

ID Station	R (km)	a_{max} (g)		Geological Setting
		N-S	E-W	
ACH1	53.2	0.32	0.19	Cuaternary marine terraces
ACH2	53.6	0.15	0.09	Piroclastics materials / Andesite / Rhyolite

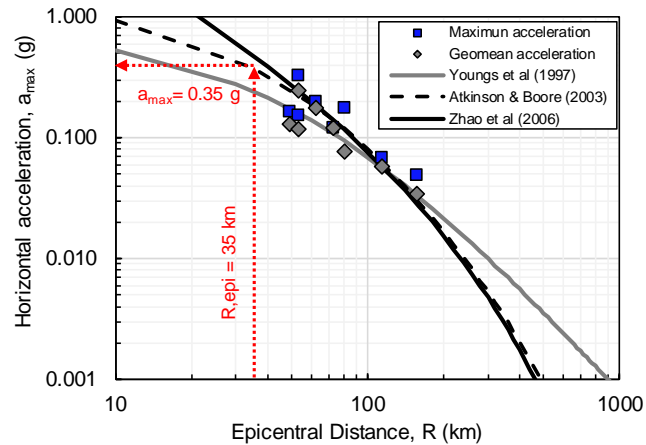

GYKA	62.5	0.2	0.16	Cuaternary marine terraces
AC07	73.2	0.12	0.12	Guayaquil Formation (siltstones/shales)
ARNL	81.7	0.18	0.03	Marine terraces / Alluvial Deposits
APLA	48.9	0.17	0.1	Tablazo Formation (sandstones)
ACUE	115	0.05	0.07	Alluvial Deposits / Sandstones
ALJ1	156.8	0.02	0.05	Quilloaco Group (siltstones)

403

404 The models selected for the evaluation were: Youngs et al. [53], Atkinson and Boore
405 [54] and Zhao et al. [55]. The GMPEs proposed by Atkinson and Boore [54] and Zhao et
406 al. [55] include site factors to evaluate the effect of the dynamic properties of the deposit
407 on the expected seismic intensities. In both cases, the chosen site parameters correspond
408 to the most unfavorable ground condition, which meant, NEHRP E or NEHRP F type
409 soils, with average shear-wave velocity for the upper 30 m depth (V_{s30}) less than 200 m/s.

410 An important difference to note is that the models proposed by Youngs et al. [53] and
411 Atkinson and Boore [54] estimate the maximum horizontal acceleration in a random
412 component, while Zhao et al. [55] estimates the geometric mean (geomean) of the two
413 horizontal acceleration components. Then, in order to validate the intensities calculated
414 by the selected models, the maximum acceleration of the two components (blue squares
415 in Figure 7) and the geometric mean acceleration (grey rhombuses in Figure 7) were
416 plotted together with the predicted acceleration from the GMPEs, as shown in the Figure
417 7. A good correlation was observed between the predicted accelerations and those
418 measured by the Ecuadorian Accelerograph Network. Therefore, their use for the
419 estimation of the maximum horizontal acceleration (a_{max}) in Puerto Baquerizo was
420 considered appropriate.

421 The epicentral distance (R) to Puerto Baquerizo site is approximately 35 km. For this
422 distance the models predict accelerations between 0.28g and 0.48 g, according to the
423 models of Youngs et al. [53] and Zhao et al. [55], respectively. Finally, the Atkinson and
424 Boore [54] equation determined a horizontal acceleration of 0.38g. For the liquefaction
425 potential analysis, the geometric mean of the three calculated accelerations was used,
426 which means, 0.35g.

427

428 Figure 7 Maximum horizontal acceleration prediction in Puerto Baquerizo in Mw6.6
 429 Balao earthquake

430 **5.3.Results and discussions**

431 The cyclic stress ratio ($CSR_{7.5, 1atm}$) was estimated between 0.30 and 0.37 using the
 432 methodology proposed by Boulanger and Idriss [3] for the sand-like layers (black and
 433 white dots in Figure 9a, Figure 9b and Figure 9c). Through Youd et al. ([52], purple
 434 dots in Figure 9d) the cyclic stress ratios ($CSR_{7.5, 1atm}$) were determined between 0.29
 435 and 0.35. These values represent between 15% and 30% less than that calculated from
 436 Boulanger and Idriss [3]. This fact is more noticeable for the results obtained from Kayen
 437 et al. [44] which report cyclic stress ratios between 0.25 to 0.27 for the sand-like soils
 438 (red dots in Figure 9d).

439 Regarding to soil liquefaction resistance evaluation, all the methods determine the
 440 $CRR_{7.5}$ between 0.10 and 0.25. Hence, the factors of safety against liquefaction were
 441 calculated between 0.25 and 0.60 for the sand-like deposits, as shown in Figure 8.
 442 According to these results, almost all the granular materials identified in the investigation
 443 program between 2.6 m and 6.5 m are classified as liquefiable.

444 However, the K_D -based methods and the Andrus and Stokoe [43] V_s -based method,
 445 report a substantial increase in the resistance calculated between 4.9 and 5.3 m depth,
 446 turning these materials as non-liquefiable for a Mw6.6 event. This condition is
 447 fundamentally related by the increase in the values of K_D and V_s up to magnitudes of 7.5
 448 and 215 m/s at this depth, respectively. This behavior is not detected in the evaluation of
 449 the $CRR_{7.5}$ by the CPT, the DMT+CPT and the V_s -based methods, identifying a
 450 continuous liquefiable layer between 2.7 and 6.3 m, and representing more conservative
 451 scenarios.

452 A first approximation of the severity of liquefaction was carried out by evaluating the
453 Liquefaction Potential Index (LPI) proposed by Iwasaki et al. [56]. Typically, the
454 estimated LPIs were ranging between 14 and 17 for the K_D -based methods, corresponding
455 to a very high susceptibility to liquefaction. These results are consistent with the LPI
456 calculated from the DMT+CPT Marchetti [41], the CPT and the V_s methods, where the
457 calculated indices were between 17 and 21.8. Only in the evaluation from Monaco et al.
458 [38] the site is classified in a lower category of severity.

459 An important observation about the results is that although the demand determined
460 from Kayen et al. [44] is 25% lower than that determined by Boulanger and Idriss [3], the
461 same difference is not observed with regard to safety factors and liquefaction potential
462 indices compared to the other selected methods.

463 From the observed distribution of the LPI with depth, it could be highlighted that all
464 evaluation methods agree that around the 70% of the contribution to the total LPI is
465 generated between 2.7 m to 6.3 m. On the other hand, the contribution to the LPI below
466 9.5 m is practically negligible. The fines content in the material ejected to the surface
467 after the Balao earthquake aligns with the average fines content estimated by Boulanger
468 and Idriss [3]. It also matches the lower bound of the estimated values using Suzuki [37],
469 considering this formula was calibrated in regions with higher liquefaction potential.

470 Therefore, considering: (i) the calculated safety factors, (ii) the distribution of the
471 liquefaction potential index and (iii) the similarity in the fines content estimated, it can be
472 deduced that the source layer of the liquefaction expressions observed at surface after the
473 Balao earthquake was precisely the non-cohesive material located between 2.7 m and 6.3
474 m.

475

476 Figure 8 Liquefaction assessment results using: K_D -based methods (DMT), V_s -based
 477 methods (SDMT), q_c -based methods (CPTu) and K_D - q_c -based methods (DMT+CPTu)

478 In order to validate the correlation of the results with the observed damages, additional
 479 parameters were determined to characterize the severity of liquefaction, such as: Ishihara-
 480 inspired Index (LPI_{ish} ; Maurer et al. [57]), Post liquefaction volumetric deformation (S_{vol} ;
 481 Zhang et al. [58]), Liquefaction Severity Number (LSN; Tonkin and Talyor, [59]) and
 482 the Induced Damage Measurement (I_{AM} ; Chiaradonna and Flora, [60])

483 Since the computation of LPI_{ish} and I_{AM} directly involves the thickness of the non-
 484 liquefiable material above the source liquefaction layer, 2.7 m and 2.9 m were considered
 485 as the thickness of non-liquefiable material in the calculation of LPI_{ish} and I_{AM} for the
 486 SDMT and CPTu methods, respectively. Additionally, in order to apply the Zhang et al.
 487 [58] methodology for the SDMT derived methods to estimate post liquefaction
 488 volumetric deformation, averages of the qc_{1ncs} calculated from the CPTu data were taken
 489 around each depth where SDMT data was available.

490

491 Figure 9 Cyclic resistance Ratio ($CRR_{7.5}$) curves for: a) K_D -based, b) qc -based, c)
 492 $qc + K_D$ -based and d) V_s -based methods, and their relation with the predicted Cyclic
 493 stress ratio ($CSR_{7.5, 1atm}$, from Boulanger & Idriss, [3]) in cohesiveness (data filtered
 494 for $I_D > 1.20$, $I_c < 2.60$ and $FC > 50\%$)

495

496 Table 3 Liquefaction Potential Index for Puerto Baquerizo estimated from SDMT and
 497 CPT test results

Method of assessment	LPI (-)	LPI _{ish} (-)	S _{vol} (cm)	LSN (-)	I _{AM} (-)
Monaco et al. (2005)	10.3	6.9	9.9	18.8	0.59
Tsai et al. (2009)	15	10.5	13.5	26.5	0.92
Robertson (2012)	14	9.9	12.3	24.1	0.77
Marchetti K _D -based (2016)	17	11.8	13.7	29	0.88
Chiaradonna and Monaco (2022)	16.6	11.9	13.4	27.5	0.84
Idriss and Boulanger CPT-based (2008)	21.8	15.3	18.7	32.6	0.85
Boulanger and Idriss CPT-based (2014)	21.4	15.1	18.1	31.9	0.85
Marchetti CPT+DMT (2016)	18.2	12.4	13.4	27.3	0.8
Andrus and Stokoe (2000)	17.5	13.7	12.1	27	0.85
Kayen et al. (2013)	17.9	13.9	13.4	30.1	0.92

498

499 The Table 3 summarizes all the severity indices determinate for each evaluation
 500 methodology. The results of LPI_{ish} and I_{AM} indicate that the severity of liquefaction would
 501 be between “High” to “Very high”, that is, a lower expected impact of liquefaction
 502 compared to the results of the Liquefaction Potential Index. This fact implies that the
 503 presence of the cohesive layer above the liquefiable stratum mitigates importantly the
 504 effects of the liquefaction at surface.

505 On the other hand, the volumetric deformations were determined in the order of 9.9
 506 cm to 18.7 cm. The q_c-based and K_D-q_c-based are the methods which calculated the
 507 highest levels of deformation, being Idriss and Boulanger [2] the model by which the
 508 maximum volumetric deformation were determinated. There is no information about the
 509 condition of site prior to the Balao earthquake, then it is not possible to verify whether
 510 the calculated settlement levels are related to what was observed on site.

511 The calculated Liquefaction Severity Number (LSN) values range between 18.8 and
 512 40, which corresponds to moderate to severe expressions of liquefaction as a consequence
 513 of the Balao earthquake. According to Tonkin and Taylor [59], zones with moderate to
 514 severe expressions of liquefaction are characterized by the presence of sand volcanoes
 515 and the development of deformations that could generate some structural damage. This
 516 description agrees with what was observed at the study site, where the presence of sandy

517 material at surface and cracks in structural and non-structural elements in buildings close
518 to the sites where the liquefaction was evident could be observed.

519 **6. Conclusions**

520 The grain-size analysis carried out on samples recovered from sand boils in Puerto
521 Baquerizo indicates that the material corresponds to non-plastic poorly graded silty sand
522 (SP-SM) and a non-plastic poorly graded sand (SP), with fines content (FC) between 4%
523 and 6%. The morphological and componentry evaluation determined that around 80% of
524 the particles studied correspond to uniform rounded grains, composed mainly of Quartz,
525 K-Feldspar, Mica, Calcite and fragments of volcanic and metamorphic rocks.

526 The results of the liquefaction assessment through methods based on SDMT and CPTu
527 indicate that Puerto Baquerizo has a “High” to “Very High” liquefaction potential. This
528 designation is consistent with the observed damage levels and expressions of surface
529 liquefaction in Puerto Baquerizo after the 2023 Mw6.6 Balao earthquake.

530 From the calculated safety factors and the distribution of the different Liquefaction
531 Potential Indices, it is deduced that the source layer of the liquefaction manifestations is
532 a 3.9 m thickness sandy layer, identified by the SMDT an CPTu approximately 2.6 m
533 below the surface. The estimation of fines contents (FC) based on correlations with the
534 Material Index (I_D) and the Soil Behavior Type Index (I_c) are higher than those measured
535 in the samples recovered at surface after the 2023 Mw6.6 Balao earthquake. However,
536 this difference could be explained through the sorting of particles diameters during the
537 material ejection process. More research is necessary to better understand the relationship
538 between the fines content of the liquefaction source layers and the composition of the
539 materials that are observed on the surface.

540 This work contributes to the understanding of the liquefaction phenomenon in
541 Quaternary soils of the Ecuadorian coast, and seems to corroborate the applicability of
542 different methodologies based on CPTu and SDMT to predict the potential and severity
543 of liquefaction in one of the most seismically active areas in the world.

CERTIFICACIÓN DE REVISIÓN DE PROYECTO DE TITULACIÓN

Por medio de la presente, Yo Davide Besenzon Venegas, Coordinador del Programa de Maestría en Geotecnia de la Escuela Superior Politécnica del Litoral (ESPOL), certifico que:

Con fecha 29 de enero de 2024, el estudiante Christian Marcelo Ramírez Carvajal con número de identificación 0930719596, de la Cohorte 5, presentó la propuesta de su tema de titulación al Comité Académico del programa. Posteriormente, con fecha 31 de mayo de 2024, el Comité revisó y aprobó la propuesta mediante la FICT-CA-GEOTEC-011-2024, cumpliendo con los requisitos establecidos para la aprobación del tema.

A partir de dicha aprobación, el estudiante mantuvo reuniones periódicas con el tutor designado, Davide Besenzon Venegas, para la elaboración y desarrollo de su proyecto de titulación, siguiendo los lineamientos establecidos por el programa. Con fecha 12 de junio de 2024, el estudiante presentó y sustentó su proyecto de titulación ante el tribunal evaluador asignado, cumpliendo con el proceso formal de evaluación académica.

Por lo tanto, en calidad de Coordinador del Programa de Maestría en Geotecnia, certifico que el trabajo de titulación denominado "**Licuação inducida por el terremoto Mw6.6 de Balao en Puerto Baquerizo (Ecuador) y su correlación con la evaluación del potencial de licuação usando SDMT y CPTu**", realizado el estudiante Christian Marcelo Ramírez Carvajal con número de identificación 0930719596, ha sido revisado y evaluado conforme a los lineamientos y estándares establecidos por el programa.

Debido a circunstancias externas, no ha sido posible obtener las firmas de los involucrados (estudiante, tutor(es) y/o evaluadores). No obstante, en calidad de Coordinador del Programa, certifico que el proyecto cumple con los requisitos académicos y ha sido revisado para su presentación y archivo institucional.

Atentamente,

Firmado electrónicamente por:
ANDRES EDUARDO
GUZMAN VELASQUEZ
